THE PARKER INSTABILITY IN AXISYMMETRIC FILAMENTS:
FINAL EQUILIBRIA WITH LONGITUDINAL MAGNETIC FIELD

F. J. Sánchez-Salcedo\(^1\) and A. Santillán\(^2\)

Received 2010 August 4; accepted 2010 November 18

Key Words: instabilities — ISM — ISM: structure — magnetic fields — MHD

1. INTRODUCTION

Parker (1966) demonstrated that a layer supported against the vertical gravity by the pressure of interstellar gas, horizontal magnetic field and cosmic rays is always unstable to long wavelength deformations of the field lines because of the buoyancy of magnetic field and cosmic rays. Much work has been done to understand the role of the Parker instability in modeling the structure of the interstellar medium (ISM) and, more specifically, its role in gathering gas to trigger the formation of giant molecular clouds (e.g., Mouschovias, Shu, & Woodward 1974; Blitz & Shu 1980; Mouschovias, Kunz, & Christie 2009). Giz & Shu (1993), Kim, Hong, & Ryu (1997) and Kim & Hong (1998) examined how the non-uniform nature of the Galactic gravity might affect the length and timescales of the Parker instability. Many studies have been devoted to investigate the effect of other physical ingredients on the Parker instability (Shu 1974; Nakamura, Hanawa, & Nakano 1991; Hanawa, Matsumoto, & Shibata 1992; Hanasz & Lesch 2000; Kim et al. 2000; Santillán et al. 2000; Kim, Ryu, &

The structure of the final static state resulting from the Parker instability was derived by Mouschovias (1974, hereafter M74) in the Cartesian model, namely, for a non-rotating layer under a vertical gravity, with a horizontal magnetic field in the initial equilibrium state. In the unperturbed state, the gas is in hydrostatic equilibrium in a stratified layer, so that all the quantities depend only on the distance from the midplane \( y \), and the magnetic field is plane-parallel and runs along the \( x \)-direction. In this two-dimensional Cartesian problem, one assumes that all the quantities are independent of the third dimension, \( z \), at any time. In the final state, the magnetic field rises in certain regions and sinks in others forming bulges and valleys. Matter loads onto the field lines by draining down from the top region of the bulge and sinking into the valleys.

So far, the final states of the Parker instability have been discussed in Cartesian models. In various astrophysical systems, however, the gas tends to form structures with other symmetries, such as filaments or elongated structures (e.g., Genzel & Stutzki 1989; Alfaro, Cabrera-Caño, & Delgado 1992; Ryu, Kang, & Biermann 1998; Conselice, Gallagher, & Wyse 2001; Salomé et al. 2006; Jackson et al. 2010). Suppose now that we have a very elongated self-gravitating filamentary structure with a magnetic field traveling along the major axis of this structure, such that it has the effective geometry of a infinite cylinder. If the filament is supported against the radial self-gravity of the system by the pressure of gas and the longitudinal magnetic field, long wavelength deformations of the magnetic field lines will allow matter to slide radially along field lines under the action of the gravitational field towards the symmetry axis, whereas the magnetic field will tends to expand in radius, through a process of magnetic buckling (see Figure 1). If the disturbances are axisymmetric, we expect the alternate formation of magnetic bottlenecks in the condensations of gas separated by portions of inflated magnetic lines or arcades, resembling a sausage mode. The final state is expected to be different from than of a vertically stratified disk such as those models currently used to study the Parker instability in galactic disks. In fact, the response of the system and the final equilibrium state depend on the adopted model: Cartesian or axisymmetric.

In this paper, we study the nonlinear final equilibria of the Parker instability of a non-rotating, cylindrical initial state. In the initial state, the magnetic field is assumed to be parallel to the axis of the cylinder, which is taken to coincide with the \( z \)-axis. The cylinder is supported against the action of a radial gravitation field \( g_R \) by the thermal and magnetic pressures (see Figure 1). We will assume that the gas is isothermal and evolves under flux-freezing conditions. For axisymmetric perturbations, all the quantities depend only on \( z \) and \( R \) (not on the azimuthal angle \( \phi \)) and hence the problem is also two-dimensional. The evolution of the Parker instability in the \((z,R)\)-plane is expected to be qualitatively analogous, in the main features, to the evolution found in the \((x,y)\)-plane for the case of a plane-parallel initial state by M74. Throughout the paper, we will use the coordinate \( z \) to denote the distance on the axis of symmetry in the axisymmetric model; it should not be confused with the third component of the Cartesian model.

The aim of this work is to compare in detail how the final distributions of density and magnetic field vary from Cartesian to axisymmetric geometry\(^3\). Accurate predictions of the nonlinear final states, an interesting problem in itself, can be very useful for the purpose of testing MHD codes. We will follow Mouschovias’ procedure (1974, 1976) to construct the final equilibrium states. Nakano (1979)

\(^3\)Note that the change in the geometry of the system is, by no means, equivalent to a coordinate transformation.
and Tomisaka, Ikeuchi, & Nakamura (1988) used the same technique to find the structure of axisymmetric magnetized clouds that can be reached from non-equilibrium spherical configurations. By contrast, we start from a cylindrical configuration in magnetohydrostatic equilibrium as those used to study the gravitational collapse and fragmentation of filamentary clouds (e.g., Nakamura, Hanawa, & Nakano 1995). In these simulations, however, the gravitational instabilities play a dominant role and not the Parker instability. In order to isolate the outcomes of the Parker instability, we will not consider self-gravity of the gas. In addition, we will also ignore the destabilizing influence of the interchange mode and the magnetic field curvature in the equilibrium states (Asséo et al. 1978, 1980; Lachièze-Rey et al. 1980), which could lead to the development of sub-states (Asséo et al. 1978, 1980; Lachièze-Rey et al. 1980), could lead to the development of substructure. The study of these instabilities requires a full magnetohydrodynamical model and they will not be discussed further here.

Our paper is organized as follows. In § 2, we describe the initial equilibrium configurations. The elliptic differential equations that give the equilibrium states under flux-freezing conditions are provided in § 3. In § 4 we compare the resulting features of the final states arising from the Parker instability in Cartesian and axisymmetric models. A summary of the results is presented in § 5.

2. INITIAL STATES

We consider first the initial state in the Cartesian model, that is, a planar layer that is supported against the vertical gravity field by the gas pressure \( P \) and a horizontal magnetic field. We will use a Cartesian coordinate system \((x, y)\), where \(x\) is the horizontal coordinate and \(y\) is the distance to the midplane of the layer, so that \(\vec{B}_0 = (B_{0,x}(y), 0)\) in the initial state. Throughout the paper, the subscript 0 signifies the initial state. Magnetohydrostatic equilibrium is satisfied if

\[
\vec{\nabla} \left( P_0 + \frac{B_{0,x}^2}{8\pi} \right) = -\rho \vec{\nabla} \psi, \tag{1}
\]

where \(\psi = \psi(y)\) is the gravitational potential. If the gas is isothermal with thermal sound speed \(c_s\) and the ratio of the magnetic to gas pressures, \(\alpha \equiv B_0^2/8\pi P_0\), is constant, the equilibrium equation reads

\[
(1 + \alpha)c_s^2 \nabla \ln \rho_0 = -\vec{\nabla} \psi, \tag{2}
\]

which has the solution

\[
\rho_0(y) = \rho_0(0) \exp \left( -\frac{\psi}{(1 + \alpha)c_s^2} \right), \tag{3}
\]

with \(\psi(0) = 0\). If the gravitational field \(\vec{g} = -\vec{\nabla} \psi\) is taken to be vertical and constant (but it reverses its direction across the midplane), we have \(\psi = g|y|\), with \(g = \text{constant} > 0\). In this particular case, the mass density decays exponentially with a typical scale \(H\) of \((1 + \alpha)c_s^2/g\), whereas the magnetic field strength decays with a characteristic scale \(2H\).

If, instead of a planar atmosphere, we assume that the gas extends to infinity along a cylinder whose axis coincides with the \(z\)-axis, and is threaded by an axial magnetic field \(B_z\), the density profile at equilibrium is:

\[
\rho_0(R) = \rho_0(0) \exp \left( -\frac{\psi}{(1 + \alpha)c_s^2} \right), \tag{4}
\]

where \(R\) is the radial distance in cylindrical coordinates and \(\psi(R)\) is the gravitational potential, with \(\psi(0) = 0\). In fact, we assume that the gravitational acceleration has only a radial component. If the radial gravitational force is taken to be constant, it holds that \(\psi = gR\). Therefore, the radial scalelength for the density is \(H = (1 + \alpha)c_s^2/g\), as in Cartesian geometry.

We see that if the gravitational potential \(\psi(y)\) in the infinite planar layer is identical to the gravitational potential \(\psi(R)\) in the cylindrical model, the profiles of density, magnetic field and gas pressure along \(y\) and \(R\) will be identical in both models. However, these systems are no longer equivalent when the Parker instability arises. In the Cartesian model, magnetic field lines are allowed to inflate only in the vertical direction, whereas the expansion of field lines as well as the contraction of matter occur radially in the axisymmetric model (see Figure 1). The question that arises is how the distributions of density, pressure and field lines in an azimuthal section [i.e. in the \((z, R)\)-plane] will look like as compared to those found in a vertical section [i.e. in the \((x, y)\)-plane] in the well-studied Cartesian model.

When studying the Parker instability at the solar neighborhood, it is common to use a local Cartesian frame where the azimuthal direction is identified with the horizontal coordinate \(x\) and the vertical direction in the Galaxy with \(y\). In the two-dimensional approximation, the third (radial) direction is ignored. As a cautionary comment, our coordinate \(R\) used throughout the paper should not be confused with the radial direction in the Galaxy.

3. THE EQUILIBRIUM EQUATIONS

If a disturbance of sufficiently long wavelength is applied along the initial magnetic field to the initial equilibrium states described in the previous section,
the Parker instability develops in time and parts of the magnetic field lines bulge outward until the tension of the field lines increases sufficiently for an equilibrium state to be established. In the final states arising from the Parker instability, the magnetic field lines are curved and the magnetohydrostatic force equation is

$$-\nabla P - \rho \nabla \psi + \frac{1}{c^2} \vec{J} \times \vec{B} = 0,$$  \hspace{1cm} (5)

where $\vec{J}$ is the current density. The coordinate symmetries of the unperturbed states (see § 2) reduce the problem to the $(x, y)$-plane in the Cartesian model and to the $(z, R)$-plane in the axisymmetric model. Under these symmetries, flux-freezing allows to transform the magnetostatic equations of equilibria into a second-order elliptic partial differential equation (Dungey 1953), conventionally called the Grad-Shafranov equilibrium equation. The beauty of this approach is that the final equilibrium states can be found with no need to solve a time-dependent problem (M74; Mouschovias 1976). In the following we give the Grad-Shafranov equilibrium equations and the boundary conditions. Details on its derivation can be found in M74, Mouschovias (1976) and Nakano (1979).

3.1. The Cartesian model

In the Cartesian layer with one ignorable coordinate, so that all quantities depend only on $(x, y)$, the magnetic vector potential can be written as $A = A(x, y)\hat{e}_z$ and then $B_x = \partial A / \partial y$ and $B_y = -\partial A / \partial x$. One can show that the scalar function $q(x, y)$, defined by

$$q = P \exp \left( \frac{\psi}{c_s^2} \right),$$

is constant on a field line at magnetohydrostatic equilibrium, and is given by:

$$q(A) = \frac{c_s^4}{2} \frac{d\tilde{m}}{dA} \left[ \int_0^{\lambda_s/2} dx \frac{\partial y(x, A)}{\partial A} \exp \left( -\frac{\psi(x, A)}{c_s^2} \right) \right]^{-1},$$

(7)

where $\lambda_s$ is the perturbation wavelength along the initial magnetic field and $d\tilde{m}$ is the mass per unit length (along the ignorable coordinate) in a flux tube between field lines characterized by $A$ and $A + dA$ and between $x = 0$ and $x = \lambda_s$ (i.e. the mass-to-flux ratio). Under flux-freezing conditions, the mass-to-flux ratio is a constant of motion and, therefore, can be determined from the initial equilibrium configuration:

$$\frac{d\tilde{m}}{dA} = \lambda_s \frac{\rho_0(A)}{B_0(A)},$$

(8)

Finally, the magnetic equilibrium equation (5) may be written in terms of $A$ as

$$\nabla^2 A = -4\pi \frac{d\tilde{m}}{dA} \exp \left( -\frac{\psi}{c_s^2} \right),$$

(9)

(Dungey 1953; M74). Once the boundary conditions are specified, equations (7) and (9) can be solved numerically by using an iterative scheme (M74).

The boundary conditions we take are the same as those in M74. The system is assumed to be periodic in $x$ and symmetric about the $x$-axis so that equation (9) is solved in the rectangle $0 < x < X_{max}$ with $X_{max} = \lambda_x/2$ and $0 < y < Y_{max}$, with the boundary conditions

$$\frac{\partial A}{\partial x} \bigg|_{x=0, X_{max}} = 0.$$  \hspace{1cm} (10)

The upper boundary must be far enough from the midplane to not affect the evolution, since a small vertical size of the computational domain suppresses the instability (e.g., M74; Mouschovias 1996). At the upper boundary we impose the condition that the field lines are not deformed, $A(x, Y_{max}) = A_0(Y_{max})$. Due to the imposed reflection symmetry about the midplane, the field line originally coinciding with the $x$-axis remains undeformed.

In the following, we provide the equations for the particular case of a constant external field. Although a uniform acceleration is only realistic at high altitudes from the midplane, we will concentrate on this case for simplicity and to facilitate comparison with some previous work that uses a constant gravitational field (e.g., M74; Mouschovias et al. 2009). A realistic model of the gravitational potential is important to derive the growth rate of the instability and the most unstable wavelength, which determines the separation of the magnetic valleys (Kim & Hong 1998: § 4.2). For now, we are mainly interested in the main conceptual features that arise in the final equilibria states when the geometry of the problem is changed, even if the adopted spatial dependence of the gravitational field lacks a strong astrophysical motivation.

As said in § 2, if the external gravitational field is constant, the gravitational potential is $\psi = g|y|$, with $g$ a positive and constant acceleration. The equations are put in dimensionless form by choosing the following natural units: $c_s^2 / g$, $c_s$ and $\rho_0(0)$, for length, velocity and density, respectively. The magnetic vector potential will be measured in units of $-2HB_0(0)$. Note that the dimensionless vertical scale is $H = (1+\alpha)$ in these units. The dimensionless equation (9) has the form

$$\nabla^2 A = \hat{Q}_{xy}(x, y; \alpha),$$

(11)
where
\[ \dot{Q}_{xy} = -\frac{1}{8\alpha(1+\alpha)^2} \frac{d\psi}{dR} \exp(-y). \] (12)

In these units,
\[ q(A) = \frac{1}{2} \int_{-\frac{\lambda_z}{2}}^{\frac{\lambda_z}{2}} dx \left[ \frac{\partial y(x, A)}{\partial A} \right] \exp[-y(x, A)] \right]^{-1}, \] (13)

where
\[ \frac{d\dot{m}}{dA} = -2\lambda_x(1+\alpha)A. \] (14)

Under a constant gravity condition, the vector potential in the plane-parallel unperturbed state is
\[ A_0(y) = \exp\left(-\frac{y}{2(1+\alpha)}\right), \] (15)

and the source term of equation (11) is
\[ \dot{Q}^{(i)}_{xy} = \frac{1}{4(1+\alpha)^2} \exp\left(-\frac{y}{2(1+\alpha)}\right). \] (16)

In this initial state, the relation between A and q is
\[ A_0(q) = q^{-1/(2\alpha)} \] (see also M74).

3.2. The axisymmetric model

Now, we consider a three-dimensional geometry with axial symmetry about the z-axis and longitudinal magnetic field \(B_\phi = 0\). The magnetic field is related to the potential vector \(\vec{A} = A(z, R)\hat{e}_\phi\) by \(B_z = R^{-1} \partial(RA)/\partial R\) and \(B_R = -\partial A/\partial z\). Under axisymmetric disturbances, the magnetic flux \(\Phi(R, z) \equiv RA\) is constant on a magnetic surface and is also a constant of the motion. In this geometry, the function q defined in equation (7) is given by
\[ q(\Phi) = \frac{c_s^2}{2\pi} \frac{dm}{d\Phi} \left[ \int_{-\frac{\lambda_z}{2}}^{\frac{\lambda_z}{2}} dz \frac{\partial R^2(z, \Phi)}{\partial \Phi} \exp\left(-\frac{\psi(z, \Phi)}{c_s^2}\right) \right]^{-1}, \] (17)

where \(\lambda_z\) is the longitudinal perturbation wavelength and \(dm\) is the mass in a flux tube between \(\Phi\) and \(\Phi + d\Phi\) and between \(z = 0\) to \(z = \lambda_z\). Again, \(q\) is a constant along field lines in equilibrium configurations. Under flux-freezing conditions, the mass-to-flux ratio is a constant of the motion, which can be determined from the initial configuration by:
\[ \frac{dm}{d\Psi} = 2\pi\lambda_z \rho_0 \frac{\mu_0}{B_0}. \] (18)

The balance of forces (equation 5) in the final magnetic configuration can be rewritten in terms of \(\Phi\) as
\[ \nabla^2 \Phi - \frac{2}{R} \frac{\partial \Phi}{\partial R} = -4\pi R^2 \frac{d\psi}{d\Phi} \exp\left(-\frac{\psi}{c_s^2}\right), \] (19)

(Mouschovias 1976; Nakano 1979). Equation (19) together with equation (17) enable us to derive \(\Phi(z, R)\) once the boundary conditions are specified. The magnetic field can be found just by simple derivation: \(B_z = R^{-1} \partial \Phi/\partial R\) and \(B_R = -R^{-1} \partial \Phi/\partial z\).

The computational domain is a rectangular box of \(0 < z < Z_{max}\) and \(0 < R < R_{max}\). Because of the symmetries of the initial and final states, the length of the computation box in the z-direction, \(Z_{max}\), is taken to be \(\lambda_z/2\), half the wavelength of the perturbation. Periodicity in z translates into
\[ \frac{\partial \Phi}{\partial z_{z=0,Z_{max}}} = 0. \] (20)

The definition of \(\Phi\) means that \(\Phi(0, z) = 0\) at any time. Assuming that the deformation of field lines can be neglected on the surface of the cylinder, we impose the condition that \(\Phi(z, R_{max}) = \Phi_0(R_{max})\).

The equivalent condition of constant gravity is to assume that the radial gravitational field is constant, i.e., \(\ddot{g} = g\dot{\hat{e}}_R\), with \(g\) a positive constant acceleration. We may use the units for distance, velocity and density described in the previous subsection. The magnetic flux will be measured in units of \(-4\pi H^2 B_0(0)\). Equation (19) in dimensionless form is:
\[ \nabla^2 \Phi - \frac{2}{R} \frac{\partial \Phi}{\partial R} = Q_zR(z, R; \alpha), \] (21)

with
\[ Q_zR = -\frac{R^2}{32\alpha(1+\alpha)^4} \frac{d\psi}{d\Phi} \exp(-R), \] (22)

and
\[ q(\Phi) = \frac{1}{2\pi} \frac{dm}{d\Phi} \left[ \int_{-\frac{\lambda_z}{2}}^{\frac{\lambda_z}{2}} dz \frac{\partial R^2(z, \Phi)}{\partial \Phi} \exp\left(-R(z, \Phi)\right) \right]^{-1}, \] (23)

where the dimensionless mass-to-flux is
\[ \frac{dm}{d\Psi} = -8\pi(1+\alpha)^2 \lambda_z \rho_0 \frac{\mu_0}{B_0} \] (24)
\[ = -8\pi(1+\alpha)^2 \lambda_z \exp\left(-\frac{R(\Phi)}{2(1+\alpha)}\right). \] (25)

By comparing equations (21)–(22) with equations (11)–(12), we see that the dynamical variable \(\Phi\) also satisfies a nonlinear elliptical differential equation, but with a differential operator and source term different from those of the equation governing \(A\) in the Cartesian model.

In order to gain some physical insight, it is useful to compute the function \(q(\Phi)\) in the initial equilibrium configurations which, of course, are solutions
of the differential equation (21). In a model with uniform radial gravitational field, the magnetic flux and the $q$-function in the unperturbed state are, respectively:

$$\Phi_0(R) = \left(1 + \frac{R}{2(1 + \alpha)}\right) \exp\left(-\frac{R}{2(1 + \alpha)}\right),$$  \hspace{1cm} (26)

and

$$q_0(R) = \exp\left(\frac{\alpha R}{1 + \alpha}\right).$$  \hspace{1cm} (27)

At small enough $R$, say $R \ll 2(1 + \alpha)$, they can be approximated by $\Phi_0(R) \approx \exp(-R/2[1 + \alpha])$ and $q_0(\Phi_0) = \Phi_0^{-2\alpha}$. Interestingly, they have exactly the same forms as $A_0(y)$ and $q_0(A)$ in the Cartesian model, respectively (see equation 15 and the very end of § 3.1). At large radii, $R \gg 2(1 + \alpha)$, or equivalently, $\ln q \gg 2\alpha$, the relationship between $\Phi_0$ and $q_0$ is $\Phi_0 \simeq (2\alpha)^{-1}q_0^{-1/(2\alpha)}\ln q_0$. Therefore, at these large $q$ values, $q$ increases with $\Phi^{-1}$ slightly faster than the rate at which $q$ increases with $A^{-1}$ in the Cartesian model ($q = A^{-2\alpha}$). In § 4, we will calculate the dependence of the function $q$ on $\Phi$ in the final axisymmetric equilibrium state. The shape of $q(\Phi)$ as compared to $q(A)$ in the Cartesian model will be also discussed.

The source term of the differential equation in the initial cylindrical configuration with constant $g_R$ is:

$$Q_{zR}^{(i)} = \frac{1}{8(1 + \alpha)^3} R \exp\left(-\frac{R}{2(1 + \alpha)}\right).$$  \hspace{1cm} (28)

By comparing equations (16) and (28), we see that $Q_{zR}^{(i)}$ has a similar dependence on $R$ as $Q_{xy}^{(i)}$ on $y$, except by the factor $R/(2 + 2\alpha)$. As a consequence, $Q_{zR}^{(i)}$ has a maximum at $2(1 + \alpha) = 2H$, whereas $Q_{xy}^{(i)}$ is a monotonically decreasing function of $y$. In order to facilitate comparison between both cases, it is convenient to use $Q_{xy}$ defined as $Q_{xy} \equiv yQ_{xy}/(2 + 2\alpha)$ because both $Q_{xy}$ and $Q_{zR}$ are identical at the initial state. However, they are expected to depart from each other in the nonlinear equilibrium state because of the changes introduced by the different geometries. The form of $Q_{xy}$ and $Q_{zR}$ in the final equilibrium states will be discussed in the next section.

4. FINAL EQUILIBRIUM STATES

The final equilibrium state can be reached from the initial configuration through continuous deformations of field lines using an iterative method as described in M74. To do so, we add a perturbation to the magnetic variables in the initial equilibrium state,

$$\delta A(x, y) = -\mu A_0(y) \sin\left(\frac{\pi y}{Y_{max}}\right) \cos\left(\frac{\pi x}{X_{max}}\right),$$  \hspace{1cm} (29)

for the Cartesian model and

$$\delta \Phi(z, R) = -\mu \Phi_0(\Phi) \sin\left(\frac{\pi R}{R_{max}}\right) \cos\left(\frac{\pi z}{Z_{max}}\right),$$  \hspace{1cm} (30)

for the axisymmetric model. Here $\mu$ is the amplitude of the perturbation which we chose between 0.02 and 0.06. Note that the perturbations are symmetric about $y = 0$ in the Cartesian model.4

Our main interest is to compare the final equilibrium states in Cartesian and axisymmetrical models using the same external gravitational potential along $y$ and $R$, respectively. In this way, the comparison can be done on a common ground. In the next subsection, we will do so for models with constant gravitational acceleration. A more realistic gravitational potential will be studied in § 4.2 in order to examine how it might affect the final nonlinear states.

4.1. Constant gravitational acceleration

Parker (1966) showed that a plane-parallel atmosphere with uniform gravity and a horizontal magnetic field is unstable to the undular mode if the horizontal wavelength of the perturbation is larger than a critical value, namely, $\lambda_x > \lambda_{crit} \equiv 4\pi(1 + \alpha)/(2\alpha + 1)^{1/2}$. For the reference value $\alpha = 1$, the dimensionless critical wavelength is 14.5 or, equivalently, $7.26H$. Magnetic tension can stabilize disturbances with shorter wavelengths. The horizontal wavelength of the mode with the maximum growth rate depends on the vertical wavelength. For a typical value of $Y_{max} = 24$, the maximum growth rate occurs at $X_{max} = 12$ (i.e. $\lambda_x = 24$).

The stability of magnetized cylinders has been considered in the past (e.g., Stodolkiewicz 1963; Nagasawa 1987) but, to our knowledge, none derived the dispersion relation under the assumption of a constant gravitational field. Nevertheless, the linearized equations of motion under axial geometry and axisymmetric perturbations are identical to equations (III-3)–(III-6) quoted in Parker (1966), once the subscripts $y$ and $z$ in Parker’s notation are replaced by $z$ and $R$, except for the curvature term $v_R/R$ that appears as an extra term in the continuity and energy equations. Since the curvature term

4The Cartesian model allows also solutions where field lines cross the midplane. They are called odd-parity solutions or midplane antisymmetric modes.
Fig. 2. Azimuthal section of the magnetic flux $\Phi(z, R)$ in the axially-symmetric final state for $\alpha = 1$ and $g_R = g = \text{const}$, when the upper boundary is placed at $R_{\text{max}} = 24$ (top) and at $R_{\text{max}} = 33.5$ (middle). Magnetic field lines coincide with the isocontours of $\Phi$. The color bar is shown in a natural logarithmic scale. The unit length is $c^2_s/g$. A comparison of the radial profile of the magnetic flux along cuts at $z = 0$ and $z = Z_{\text{max}}$ is given in the lower panel when the boundary is located at $R_{\text{max}} = 24$ and $R_{\text{max}} = 33.5$.

becomes small at scales comparable or larger than $\lambda_{\text{crit}}$, the critical wavelength is essentially the same in both geometries. In fact, we have checked that our iterative scheme converges to the initial state as long as $\lambda_z \lesssim 7.5H$ (when $\alpha = 1$ is used), indicating that they are stable.

In the Cartesian atmosphere, M74 found that if the upper boundary is far enough from the galactic plane, i.e. $Y_{\text{max}} \gg (1 + \alpha)$ in dimensionless units, the evolution of most of the matter in the domain is not affected by the location of the upper boundary. The reason is that more than 90% of the energy of the initial state resides under $y < 3(1 + \alpha)$ (see M74). In the axisymmetrical model, we can apply the same reasoning to expect that the solution is not significantly altered as long as the box size is much larger than the effective scaleheight, defined as the radius $R$ at which $\Phi_0$ decays by a factor $e$, namely, $4.3(1+\alpha)$ [note that the effective scaleheight of $A_0$ in the Cartesian model is $2(1+\alpha)$]. In Figure 2 we compare the the magnetic flux of the final state in the axisymmetrical model using $\alpha = 1$ and $\lambda_z/2 = 12$, when the upper boundary, $R_{\text{max}}$, is located at 24 and at 33.5. We see that both maps are almost identical at $R < 20$. The main difference is that the upper magnetic field lines in the magnetic bulge region inflate further out when the boundary is far away, because a larger column of material is unloaded and brought down to the valley of the curved magnetic field lines. Therefore, this upper region becomes lighter and more buoyant. By contrast, cuts of $\Phi$ along the valley $z = 0$ are very similar in both cases (see the lower panel of Figure 2). This means
that the extra material that has been loaded into the valley when the upper boundary is placed at 33.5, does not cause significant additional compression in the radial direction.

In order to have the same dynamical range in all our calculations, we will place our upper boundary at the distance at which the variable of interest (\(A\) for the Cartesian model and \(\Phi\) for the axisymmetric case) decreases to \(\exp(-6.12) = 0.0022\) of its maximum value. With this convention, \(Y_{\text{max}} = 12.2(1 + \alpha)\) and \(R_{\text{max}} = 16.7(1 + \alpha)\). Interestingly, in the axisymmetric case, the corresponding density at \(R_{\text{max}}\) is only \(5.4 \times 10^{-8}\) of its value at \(R = 0\).

Different magnetostatic equilibrium configurations can be found by choosing the function \(q(A)\) for the Cartesian model and \(q(\Phi)\) for the axisymmetric one. Parker (1966) explored the cases in which \(q(A)\) is either a linear or quadratic function of \(A\). In practice, these functions are not free because they are defined by the initial conditions. M74 emphasized that \(q\) increases when \(A\) decreases in the Cartesian model. In Figure 3, the functions \(q(A)\) for the Cartesian layer and \(q(\Phi)\) for the axially-symmetric configuration are plotted for \(\alpha = 1\) and \(\lambda_x/2 = \lambda_z/2 = 15\). In the initial state, the function \(q_0(A)\) follows a power-law with index \(-2\alpha\) (see § 3.1 and Figure 3). In the final equilibrium state, the power-law index varies with \(A\), but \(q(A)\) is always a monotonically decreasing function. As discussed in § 3.2 and shown in Figure 3, the slope of \(q\) in the initial state of the axisymmetric model is steeper than in the Cartesian model. In fact, \(q_0\) reaches a maximum value of \(10^{7.3}\) in the axisymmetric model, but only \(10^{6.2}\) in the Cartesian model. Note that the range of the \(q\)-axis in Figure 3 spans somewhat different values in order to facilitate comparison of the shape of the curves. The behavior of \(q\) versus \(\Phi\) in the final equilibrium state is similar to that of \(q\) versus \(A\) (see Figure 3), although the new geometry introduces some remarkable differences in the shape of the function \(q(\Phi)\). For instance, the change of \(q\), relative to its initial value, in the range \(0.6 < \log_{10} \Phi^{-1} < 1.5\) is smaller than in the same range of \(A\) in the Cartesian model. The similar appearance of the functions

Fig. 4. The dependence of the functions \(Q_{xy}\) and \(Q_{zR}\) on \(y\) and \(R\), respectively in the initial states (dashed lines) and in the final states (solid lines), with \(\alpha = 1\) and constant gravity. In the left panels, \(Q_{xy}\) is shown along the lines \(x = 0\) and \(x = X_{\text{max}}\) for two different wavelengths: \(\lambda_x/2 = 9\) and 15. The right panels display \(Q_{zR}\) along the lines \(z = 0\) and \(z = Z_{\text{max}}\) for \(\lambda_z/2 = 9\) and 15, as quoted in the corners of these panels.
Fig. 5. Color map of the magnetic flux $\Phi(z, R)$ in a natural logarithmic scale for the final state for $\lambda_z/2 = 12$ (in dimensionless units) and different values of $\alpha$. The radial gravitational acceleration $g_R$ was assumed to be constant.

$q(A)$ and $q(\Phi)$ should not lead us to the false conclusion that the source terms of the elliptic differential equations, namely $Q_{xy}(x, y)$ and $Q_{zR}(z, R)$, are also similar. Figure 4 displays $Q_{xy}$ at two different cuts along $x = 0$ and $x = X_{\text{max}}$, and $Q_{zR}$ along $z = 0$ and $z = Z_{\text{max}}$. The fractional change of $Q_{xy}$ from its initial value is always larger than the change of $Q_{zR}$. Both $Q_{xy}$ and $Q_{zR}$ may present two local maxima along a cut through the maximum heights of the magnetic field lines, i.e., along $x = X_{\text{max}}$ and $z = Z_{\text{max}}$. The relative amplitude of these maxima varies with the wavelength of the perturbation.

Figure 5 shows contour plots of the magnetic flux in the final axisymmetric state for a disturbance with $\lambda_z/2 = 12$ and three different $\alpha$ values ($\alpha = 0.7, 1.0$ and $1.4$). We see that the maps are a scaled version of each other by the factor $1 + \alpha$. Since it is common for astrophysical purposes to assume equipartition between magnetic field and gas pressures, we will restrict ourselves to the case $\alpha = 1$ hereafter.

Figure 6 exhibits contour plots of the density (color image) and magnetic field lines in the final stable state of the axisymmetric model for three different horizontal wavelengths ($\lambda_z/2 = 9, 12$ and $24$). For comparison, density and magnetic field lines are also shown for the Cartesian model. Although the vertical size of the computational domain is larger in the axisymmetric case, we show the same box in all the cases for ease in visualization. When the systems are disturbed with the same wavelength, it is clear from Figure 6 that the field lines and the density contours become more deformed in the Cartesian model than under axial symmetry. It turns out that a cylindrical initial configuration is more rigid to perturbations and the magnetic field is less buoyant than a plane-parallel layer. Interestingly, the same degree of deformation of magnetic field lines found for $\lambda_z/2 = 9$ in the Cartesian model, can be achieved in the axisymmetric case but for a longer wavelength of $\lambda_z/2 = 12$. Likewise, the level of radial buoyancy of the magnetic field for $\lambda_z/2 = 15$ is comparable to the level of vertical buoyancy for $\lambda_z/2 = 12$ in the Cartesian model.

The column density map of a filament with $\alpha = 1$ and whose axis of symmetry lies in the plane of the sky is given in Figure 7 in the initial and final equilibrium states with $\lambda_z/2 = 15$. The scaleheight of the column density along a condensation in the direction perpendicular to $z$ is about twice the scaleheight in the wings of the condensations. As a consequence of the less efficient drainage of gas into the magnetic valleys, the column density enhancement in the gas condensations is rather modest. In fact, the maximum enhancement in the column density over a line of sight with zero impact parameter is smaller than in the Cartesian model (see Figure 8). The column density may increase up to a factor of $7/4$ in Cartesian geometry (see also Kim, Ryu, & Hong 2004) but only by a factor of $5/4$ in the axisymmetric model.

The result that a cylindrical configuration is more rigid than a plane-parallel layer has, a posteriori, a simple geometrical explanation, as follows. Since magnetic forces act only perpendicular to the field lines, gas pressure gradients must balance the gravitational forces along a field line regardless the ge-
Fig. 6. Color contour plots of the density and magnetic field lines (solid lines) for the Cartesian model (left) and the axisymmetric model (right), under constant gravity, for half the wavelength of 9, 12 and 15 in units of $c_s^2/g$ (from top to bottom) and $\alpha = 1$. The color bar gives the correlation between the colors and the natural logarithm of the density. The number on some curves is the value of $A$ in the Cartesian model or the value of $\Phi$ in the axisymmetric model. To make the comparison of the deformation of the magnetic field lines easier, we plot the same magnetic lines in both models.

geometry of the problem. The plasma must slide down along the magnetic field lines until it reaches a new configuration of pressure equilibrium. The point is that, because of the radial convergence of the flow streamlines in the axisymmetrical model, we need less displacement of gas in the axisymmetric case than in the Cartesian model to achieve the same pressure gradient, as soon as the gas is isothermal, and, henceforth, less deformation of the magnetic field lines.

Since the separation between magnetic field lines in azimuthal sections do not reflect the magnetic strength in the axisymmetric case, it is illustrative to compare the magnetic pressure to make a fair comparison between the results in Cartesian and axial geometries (see Figure 9). Given a certain wavelength of the perturbation, the magnetic pressure maps depend on the geometry. Because of the stronger deformation in the Cartesian scenario, the magnetic pressure force and the magnetic stresses along the valleys of the magnetic field lines, i.e. at the cut $x = 0$, are larger than along $z = 0$. The distribution of magnetic pressure in the axial model with $\lambda_z/2 = 12$ is quite similar to the magnetic pressure configuration in the Cartesian case with $\lambda_x/2 = 9$.

The ratio of the magnetic to gas pressures is an indicator of the efficiency with which gas flows along field lines. As the increase of gas density in the magnetic field valleys is due primarily to the drainage along the field lines (see also M74), we expect that if the drainage is less efficient in the axisymmetric-
Fig. 7. Column density map for the initial (top panel) and final axisymmetric state (bottom panel) along a line of sight perpendicular to the axis of symmetry (z-axis). We used $\alpha = 1$, $\lambda_z/2 = 15$ and uniform radial gravity. The units of surface density and length are $\rho_0(0)c^2_s/g$ and $c^2_s/g$, respectively. Note that the scale is linear.

In the final case, the variation of $\alpha$ in the final state relative to the initial values should be also smaller. In Figure 10, we plot the distribution of the magnetic-to-gas pressure ratio along $x = 0$ and $x = X_{\text{max}}$ for the Cartesian model, and along the same cuts $z = 0$ and $z = Z_{\text{max}}$ for the axisymmetric model in the final state, for a perturbation with half the wavelength of 15. Although the general shape of the curves is rather similar in both geometries, the $\alpha$ values in the range $10 < y < 22$ at $x = X_{\text{max}}$ are almost a factor of 10 larger than in the axisymmetric model at the same region (i.e. $10 < R < 22$ and $z = Z_{\text{max}}$).

4.2. Non-uniform gravitational acceleration

In an infinite self-gravitating isothermal filament, the gravitational acceleration $g_R$ at large $R$ decays as $1/R$, whereas it increases linearly at small $R$. Therefore, the assumption that $g_R$ is constant is only valid at some intermediate range in $R$. To close our analysis, in this subsection we present the final equilibria for axially-symmetric configurations in a more realistic external gravitational field.

According to the results of Kim & Hong (1998) for a Cartesian model, the growth time is reduced by almost an order of magnitude and the length scale of the most unstable mode by factors of $4-8$ when a more realistic gravity model is used, because in such a realistic disk the magnetic field strength decreases rapidly with vertical distance which promotes the development of strong magnetic buoyancy. We expect, therefore, that the length and timescales of the Parker instability in a filament will be modified if a more realistic gravity model is adopted.

In order to have a model as self-consistent as possible, we will assume that the external gravitational potential is dominated by a collisionless (stellar or dark matter) component with isothermal one-dimensional velocity dispersion $\sigma_\star$. The gravitational potential created by an isothermal filament is given by

$$\psi(R) = 2\sigma_\star^2 \ln \left(1 + \frac{R^2}{8H_*^2}\right), \quad (31)$$

where $H_\star$ is a parameter that specifies the scale height of the collisionless component satisfying $4\pi G \rho_{0,\star}(0) H_\star^2 = \sigma_\star^2$, where $\rho_{0,\star}(0)$ is the density of collisionless matter at $R = 0$ (e.g., Ostriker 1964).

As already anticipated, the gravitational acceleration $g_R(R)$ increases linearly with $R$ at $R \ll \sqrt{8H_\star}$, reaches a maximum at $\sqrt{8H_\star}$ and decreases as $1/R$ at $R \gg \sqrt{8H_\star}$. Under this gravitational field, the density and magnetic field in the unperturbed state...
are:
\[
\frac{\rho_0(R)}{\rho_0(0)} = \frac{B^2_0(R)}{B^2_0(0)} = \left(1 + \frac{R^2}{8H^2_2}\right)^{-s},
\]  
(32)
where \(s\) is defined by \(s \equiv 2\sigma^2/[\alpha c_s^2]\). If we define the scale height of the gas, \(H\), as the radial distance at which the density of the gas is reduced to \(1/e\) of its value at \(R = 0\), then \(H^2 = 8(\exp(1/s) - 1)H^2_2\).

To illustrate the effect of using a non-constant gravitational acceleration, we used \(\alpha = 1\) but different values of \(s\). We ran models where the upper cap was located at the distance \(R_{\text{max}}\) at which the density decreases to \((1 - 5) \times 10^{-6}\) of its value at \(R = 0\). We have empirically derived that the larger the \(s\)-value is, the smaller the critical wavelength becomes. For \(s = 4\), perturbations with \(\lambda_z/2 = 3.85H_2 = 2.55H\) are marginally unstable, whereas they become marginally unstable at \(\lambda_z/2 = 1.5H\) when \(s = 8\). In terms of \(H\), this result implies that the critical wavelength for \(s = 4 - 8\) is smaller by almost a factor of \(1.5 - 2.5\) than that for the model with constant gravity (see \(\S\) 4.1) and, therefore, the growth timescale is shorter for larger \(s\)-values. Figure 11 shows the final equilibrium state for \(s = 4\) and \(\lambda_z/2 = 5.3H\). This \(\lambda_z\)-value is close to the horizontal wavelength with maximum growth rate. By comparing with Figure 6, we note that although the global appearance is similar to the case with constant gravity and \(\lambda_z/2 = 15\), the field lines appear slightly more deformed. The main effect of a non-constant gravitational acceleration strength is to shorten the separation of the magnetic valleys. The projected surface density that an observer would see if the axis of the filament lies in the plane of the sky is shown in Figure 12 for a model with \(s = 4\). The enhancement in the column density over a line of sight passing through the core of a condensation is \(2.1\) in this model. This factor is appreciably larger than...
Fig. 10. Decadic logarithm of the ratio between the magnetic and gas pressures in the final state under constant gravity condition. The two solid lines give $\alpha$ values along the lines $x = 0$ and $x = X_{\text{max}} = 15$ for the Cartesian model and the dashed lines give $\alpha$ along $z = 0$ and $z = Z_{\text{max}} = 15$ in the axisymmetric case.

that obtained in axisymmetric models with constant gravity but similar to that found in Cartesian models with uniform gravity.

5. DISCUSSION AND CONCLUSIONS

The Parker instability dictates that longitudinal magnetic field lines that give some support against gravity are always unstable to undular perturbations. It has long been realized that the Parker instability, which is interesting in itself, may play a significant role in understanding the formation of massive clouds in the interstellar medium, probably aided by thermal and gravitational instabilities (Mouschovias et al. 2009). The Parker instability can also play a role in the evolution of filamentary structure, such as filamentary clouds, at least at the early stages of the instability. While the properties of the final states are well documented for Cartesian models (e.g., M74; Basu, Mouschovias, & Paleologou 1997; Kim et al. 2001), it was unclear how they depend on the adopted geometry. In order to fill this gap, our primary goal was to investigate the nonlin-

Fig. 11. Distribution of the volume density and magnetic field lines in the axisymmetric final equilibrium state in a non-uniform radial gravitational field with $s = 4$. In order to facilitate comparison with Figure 6 in which $H = 2$, distance is measured in units of $H/2$. Field lines (solid curves) were chosen so that they have the same magnetic strength in the initial state as those displayed in Figure 6.

Fig. 12. Column density map for the final axisymmetric state along a line of sight perpendicular to the axis of symmetry ($z$-axis). We used $\alpha = 1$, $s = 4$ and $\lambda_z = 21.3$. The units of density and length are $\rho_0(0)$ and $H/2$, respectively. Note that the scale is linear.

ear outcome of such an instability in an axisymmetric model where the initial equilibrium configuration consists of an infinite cylinder in the presence of a longitudinal magnetic field. We quantified the level of buoyancy of the magnetic field and drainage of the gas to promote density enhancements, as compared to the Cartesian models, which are currently being used to study the formation of substructure in the interstellar medium. We focused on understanding the physics of the Parker instability in filaments, rather than on making detailed comparisons with ob-
servations. This may be very useful as a first step to interpret full numerical simulations.

In the Cartesian model, the potential vector function $A$ obeys a nonlinear elliptic equation, while for the axisymmetric model it is the magnetic flux $\Phi$ that obeys such equation. However, the differential operator as well as the source terms are different. In order to gain some insight on the different nature of the equations, we have compared the form of $q(A)$ and $q(\Phi)$ at the initial and final states in each model. The source terms depend directly on the derivatives of these functions. However, despite the fact that the aspect of these functions looks similar at a glance, the source terms $Q_{xy}$ and $Q_{zR}$ turn out to be absolutely different in the final state. This is a consequence of the nonlinearity of the differential equations.

We have focused first on models with uniform external gravity. We found that the axial model is more rigid than the Cartesian layer, in the sense that the magnetic field is less buoyant and the drainage of gas less efficient. In fact, in the axisymmetric model the matter shrinks in radius and generates a convergent flow that facilitates the achievement of pressure equilibrium with less deformation of the field lines. In order to have the same level of deformation of the field lines as in the Cartesian model with half the wavelength of $9c_s^2/g$, we need a perturbation of half the wavelength of $12c_s^2/g$, for $\alpha = 1$. Under uniform gravity, we find that a factor $5/4$ enhancement in column density can be obtained in the axisymmetric model for the more unstable wavelength, which is modest as compared to the factor of $7/4$ found in the Cartesian model. At the position of the wings of the condensations, the ratio of the magnetic-to-gas pressure becomes larger than $1$ beyond a certain radius, because of the evacuation of gas in these regions. However, it is still approximately $10$ times smaller than in Cartesian geometry.

We have examined a more realistic choice to describe the variation of the external gravitational potential in axisymmetric models. The main effects of a non-uniform gravitational acceleration is to modify the separation of magnetic valleys and therefore the timescale of the Parker instability. A factor of $2$ enhancement in column density over its initial equilibrium value can be found in axisymmetric models with non-uniform radial gravity. Hence, unless this density enhancement is sufficient to initiate thermal or gravitational instabilities, the Parker instability should be thought of as setting the stage upon which other small-scale processes will be modeling the structure and evolution of the filament.

We would like to thank José Franco and Jong-soo Kim for helpful comments and the anonymous referee for very valuable suggestions, which have led to substantial improvements to the manuscript. The authors acknowledge financial support from Conacyt project CB-2006-60526 and PAPIIT project IN121609.
