ABSTRACT

Crustal stretching affecting western Mexico during the Neogene, and its relationship with the opening of the Gulf of California, has been widely studied and discussed for several decades. Nevertheless, the timing and kinematics of the opening is a matter of debate. Most authors essentially agree in considering the rupture of the lithosphere around the Gulf of California, as a fast process that began at ~12.5 Ma and became successful in the early Pliocene, when new oceanic crust began to form in the southern Gulf of California. However, recent studies demonstrated that the crustal stretching processes leading to the Gulf opening began in Late Oligocene as a wide rift, which subsequently focused into the present Gulf area in the early Miocene, accompanied by a slight change in the direction of extension. Eventually, after subduction ceased, highly oblique transensional deformation broke the previously extended lithosphere.

In this work we present a structural study of the kinematics and time of faulting, and of mafic dikes along three transects in the southern Sierra Madre Occidental, along the southeastern margin of the Gulf. We found that the deformation associated with the beginning of the Gulf of California rifting can be grouped in three sets: 1) normal faults formed during a first phase of deformation, beginning at ~24 Ma, characterized by E-W extension; 2) normal faults and dikes formed between ~20 and 11 Ma, associated with a second deformation phase, with ENE-WSW extension; 3) E-W to NE-SW oblique slip and strike-slip faults and dikes, associated with rift accommodation zones that segment the Gulf of California rift. No significant deformation occurred in the study area after 11 Ma, time at which the extension focused in the present Gulf region. The kinematics of faulting in the study area excludes that significant oblique or lateral deformation might have occurred during the initial phase of rifting in the southern Gulf of California, coincident with the last phase of subduction.

Key words: Sierra Madre Occidental; extensional tectonics; kinematics; Miocene; Gulf of California; Mexico.

RESUMEN

El proceso de extensión cortical de la margen occidental de México durante el Neógeno y su relación con la apertura del Golfo de California ha sido estudiado y discutido por varias décadas. Sin embargo la temporalidad y la cinemática de esta apertura son temas todavía debatidos. La mayoría de los autores concuerdan en que la ruptura de la litósfera en el Golfo de California fue un proceso rápido que inició a los ~12.5 Ma, para culminar al principio del Plioceno, cuando comienza el proceso de oceanización en las cuencas de la parte sur del Golfo. Sin embargo, trabajos recientes han demostrado que el proceso de extensión cortical que llevó a la apertura del Golfo comenzó desde el Oligoceno tardío a manera de un rift amplio, para posteriormente focalizarse en la zona del futuro Golfo de California en el Mioceno inferior, acompañado de un ligero cambio en la dirección de extensión. Finalmente, después del término de la subducción, la deformación transtensional fuertemente oblicua terminó de romper la franja de litósfera previamente extendida.

En este trabajo se presenta un estudio estructural de la cinemática y la temporalidad del fallamiento, y de los diques maficos a lo largo de tres transectos en la zona suroccidental de la Sierra Madre Occidental, la cual constituye la margen surooriental del Golfo. Los resultados indican que las estructuras observadas se pueden agrupar en tres familias: 1) fallas normales asociadas a una primera fase de deformación que comienza hacia los ~24 Ma, y se caracteriza por una extensión con dirección E-W; 2) fallas normales y diques, entre ~20 y 11 Ma, asociados a una extensión orientada en dirección ENE-WSW, ortogonal al eje del Golfo de California; 3) fallas oblicuas y laterales, y diques de dirección E-W a NE-SW que se asocian a zonas de acomodo que segmentan transversalmente al rift del Golfo de California. Cabe mencionar que no hay deformación significativa después de los 11 Ma, tiempo en que la extensión se concentra en la región actualmente ocupada por el Golfo. La cinemática asociada al fallamiento observado indica movimientos dominantemente de tipo normal, lo cual excluye la posibilidad de que se hayan acomodado movimientos oblicuos o laterales durante las primeras etapas de apertura del Golfo de California, ocurridas durante la fase final de la subducción.

INTRODUCTION

The age and kinematics of the extensional deformation that led to the formation of the Gulf of California is a matter of debate. Early studies proposed that in the middle to late Miocene the lithosphere in the area, called “proto-Gulf”, was rheologically weakened by the previous (early/middle Miocene) arc-volcanism, a feature that was subsequently exploited by strike-slip and extensional faulting that led to the Gulf of California opening (Karig and Jensky, 1972; Umhoefer, 2011). Later, Stock and Hodges (1989) proposed that the initial phase of opening of the Gulf of California began in late Miocene (ca. 12 Ma) and was partitioned into strike-slip motion along the Tosco-Abreojos fault system, west of Baja California, and orthogonal extension (WSW-ENE) in a broadly NNW belt along the main Gulf axis. Subsequently, beginning near the end of the late Miocene (ca. 6 Ma), the main deformation focused east of Baja California and transtensional deformation produced the final rupture of the lithosphere and the oblique opening of new oceanic basins.

Further studies in Sonora and Baja California questioned the initial partitioning of deformation proposed by Stock and Hodges (1989) and led to alternative models, which state that the deformation inside the Gulf was characterized by right-lateral transtension since ~12.5 Ma, with a smaller component of right lateral motion accommodated west of Baja California along the Tosco-Abreojos fault system (e.g. Gans, 1997; Fletcher et al., 2007). Recently, Bennett et al. (2013) proposed a hybrid model of rifting, in which the deformation along the northern Gulf was focused on a right-lateral shear zone, which later evolved into a transtensional plate limit, forming the Gulf of California rift (Bennett, et al., 2013; Bennett and Oskin, 2014). All these models, however, agree on placing the initiation of the regional dextral-oblique Pacific-North America relative plate motion at ~12.5 Ma, when the subduction of the Farallon plate remnants under North America ceased and Baja California began to be transferred to the Pacific Plate (Atwater and Stock, 1998).

More recent studies of the regional geology of northern Nayarit and Sinaloa demonstrated that extensional faulting began much earlier than the end of subduction at ~12.5 Ma (Ferrari et al., 2013). These authors shown that extension in the south-western part of the Sierra Madre Occidental (SMO) is as old as late Oligocene to early Miocene and likely controlled the style and composition of volcanism. Based on the reconstruction of the paleo-position of Baja California, Ferrari et al. (2013) also proposed that the early extension (24 to 18 Ma) in northern Nayarit and southern Sinaloa was almost orthogonal to the margin of the southern Gulf (southern Sinaloa and Nayarit) (see their fig. 15) predicting a minor component of right lateral motion, if any, in this region. This deformation is very similar to that of Sonora, where a 250 km wide belt in the western SMO was extended between late Oligocene and middle Miocene (McDowell et al., 1997; González-León et al., 2000; Vega-Granillo and Calmus, 2003; Nourse et al., 1994; Wong et al., 2010; Murray et al., 2013). Following Ferrari et al. (2013), in this work we consider that the Gulf of California rift is the result of a long period of crustal thinning that began in the late Oligocene, and became highly oblique once Baja California started moving with the Pacific plate after the end of subduction (ca. 12.5 Ma).

Here, we present a geologic and structural study of the southwestern part of the SMO in Nayarit, which constrains the kinematics of the early deformation in the southeastern flank of the Gulf of California rift. We describe the stratigraphy, as well as the geometry, kinematics and age of faulting along three transects that run almost orthogonal to the main fault systems of this part of the SMO. We found that faulting and volcanism occurred concurrently during the early Miocene under an E-W to ENE-WSW extensional stress regime. Strike slip deformation is very minor, apart from the accommodation zones that segmented this part of the rift.

GEOLOGICAL AND TECTONIC SETTING

The study area is located within the SMO, which constitutes the largest silicic igneous province in North America and the most recent event of this kind on Earth (Ferrari et al., 2007, Bryan and Ferrari, 2013). A distinctive trait of the SMO is the thick late Eocene to early Miocene ignimbrite cover that caps most of the province, traditionally known as the Upper Volcanic Supergroup (UVS, McDowell and Keizer, 1977). The UVS overlies the so-called Lower Volcanic Complex (LVC), constituted by a series of Late Cretaceous to early Eocene batholithic rocks and intermediate lavas, partly coeval with the Peninsular Range Batholiths of Baja California (McDowell and Clabaugh, 1979; McDowell et al., 1997).

The UVS was emplaced approximately between 38 and 18 Ma, with a minimum estimated volume of ~400,000 km$^3$ of dominantly rhyolitic ignimbrites (~85%) and lesser rhyolitic domes and basaltic lavas. Geochronologic studies have revealed that ignimbrites were erupted in short time spans, with peaks of over 1 km thick ignimbrite sequences emplaced in less than 1 m.y. (Swanson et al., 2006; Ferrari et al., 2002, 2007), implying a high rate of magma generation and eruption (Bryan et al., 2008; Bryan and Ferrari, 2013). Two main flare-up episodes are recognized at ~34–28 Ma and ~24–18 Ma (Ferrari et al., 2007). The Oligocene episode (~34–28 Ma) forms three-quarters of the total erupted volume, covering ~400,000 km$^3$ of the SMO (Figure 1). The Miocene ignimbritic pulse (~24–18 Ma) is concentrated in the southwestern and western part of the SMO and Baja California (Figure 1) (Sawlan and Smith, 1984; Umhoefer et al., 2001; Drake, 2005; Ferrari et al., 2002, 2007). During this period, volcanism was bimodal, with massive rhyolitic ignimbrites and rhyolitic domes accompanied by basaltic lavas that erupted from fissures, concurrently with extensional faulting (Ferrari et al., 2013). Recent studies in the southern Gulf of California documented the occurrence of early Miocene granitoids and ignimbrites on continental blocks that make up the submerged rifted margins of the Gulf of California rift, suggesting that the source area of the Miocene ignimbrites was located not only in the western side of the SMO but also within the proto-Gulf area (Ferrari et al., 2013; Duque-Trujillo et al., in press).

The central part of the SMO in western Durango and southwestern Chihuahua is characterized by a plateau of flat lying ignimbrites, which appear unaftaulted (Henry and Aranda-Gómez, 2000; Ferrari et al., 2007). On both flanks of this unextended core, extensional fault systems tilted the ignimbrite succession in different directions. Geophysical studies indicate a crustal thickness of 40 to 55 km in the unextended core of the SMO (Couch et al., 1991; Bonner and Herrin, 1999), which decreases to ~22–26 km on the extended western flank, adjacent to the Gulf of California (Persaud et al., 2007; Lizzarralde et al., 2007; Savage and Wang, 2012) (Figure 1). The extensional fault systems along the western flank of the SMO, in Sonora, Sinaloa, and northern Nayarit are part of the so-called Gulf Extensional Province (GEP), whose onset has been now dated as early as late Oligocene (Murray et al., 2013; Ferrari et al., 2013). Along this belt, ignimbrites are tilted to the ENE or WSW in domains separated by ~ENE-WSW accommodation zones (Stewart, 1998; Ferrari et al., 2007, 2013). Based on the dominant dip direction, tectonic transport direction during rifting, and the type of basement, Ferrari et al. (2013) divided the southern SMO into three different domains bounded by accommodation zones where the structural style changes and dip polarity reverses. The studied area is located in the northern Nayarit domain.
as defined in Ferrari et al. (2013), which is bounded to the south by El Roble accommodation zone (Figure 2), a left-lateral shear zone, and to the north, by the Mezquital accommodation zone, which separates opposite tilting of strata (ENE to the south and WSW to the north). Within the northern Nayarit domain, ignimbrites dominantly dip E to ENE due to N-S to NNW-SSE striking west dipping normal faults (Figure 2). Deformation within the northern Nayarit domain can be further separated into eastern and western zones.

The eastern part of the northern Nayarit domain is characterized by N-S striking high-angle normal faults that affect almost the entire domain, forming several graben and half graben structures (Figure 1). This deformation, bracketed between ca. 24 and 18 Ma, took place during the first phase of rifting that affected a wide region of the SMO (Ferrari et al., 2013). The western limit of this early extension is difficult to establish because of younger faulting affecting the southeastern margin of the Gulf of California and because structures are probably buried in the coastal plain and offshore in the continental platform. Nevertheless, early Miocene plutons, exposed along the Nayarit coast, on islands just offshore of southeastern Baja California, and on the rifted blocks submerged under the Gulf of California waters, indicate rapid cooling before ~18 Ma, during a major phase of crustal thinning (Duque-Trujillo et al., in press).

The western deformation zone of the northern Nayarit domain is characterized by a 20 km wide and ~160 km long NNW striking belt of extensional fault systems developed along the western margin of the SMO (Pochotitán and San Pedro-Acaponeta fault systems, Figure 2), which accommodated up to ~1.7 km of vertical displacement. These fault systems tilt the 21 to 18 Ma old ignimbrites and rhyolitic lavas up to 35° down to the ENE. The observed field relationships and available ages, indicate that the activity of these fault systems began after ~21 Ma, and they possibly acted as conduits for easy ascent to the surface of small volumes of silicic magmas that extruded as domes or formed subvolcanic intrusions dated between 20 and 17 Ma (Ferrari et al., 2002, 2013). The upper age of these faults is constrained by several 11 to 10 Ma old flat-lying basaltic lavas emplaced along the Nayarit coast that unconformably overlie the SMO ignimbrites. Vertical to very gently dipping, NNW striking mafic dikes of the same age are also intruded parallel to the Pochotitán and San Pedro-Acaponeta fault systems (Righter et al., 1995; Henry and Aranda-Gómez, 2000; Ferrari et al., 2000a, 2002, 2013).
LOCAL GEOLOGY

We closely examined the fault systems along the western flank of the southern SMO, following three transects, which cross the main structures along roads that were recently enlarged and paved, so that fault planes are well exposed along roadcuts (Figure 2 and 3a–3m). A brief description of the geology along these transects (Figures 4 to 6) is given in the following. Geological cross sections (Figure 7) were drawn using information gathered during fieldwork, Google Earth observations, and information compiled from previous works (Ferrari et al., 2002, 2013; SGM, 1998 and 1999).

Northern transect: Estación Ruiz – Jesús María

The Estación Ruiz–Jesús María transect runs approximately in a WSW–ENE direction between the coastal plain and the core of the SMO (Figure 2). It crosses the San Pedro–Acaponeta fault system and the southern part of the Nayar caldera, ending in the Jesús María half graben (Figures 2, 4 and 7a). The oldest rocks of the SMO province are exposed in the lowest part of the sequence on both western and eastern sides of the transect (Figure 7a). These are composed of red-brown sandstones and conglomerates (Emvs) rich in andesitic clasts, conglomeratic sandstones, and sandstones interbedded with andesitic lava flows and some thin ignimbrites (Emig) (Figure 3a-3b). Based on crude layering, it can be inferred that this sequence dips ~20° to the east, both on the western and eastern sides of the transect. These deposits are usually too weathered to be dated and are inferred to be of Paleocene to Eocene age in the Mexican Geological Survey geologic maps (SGM, 1996, 1998, 1999, 2006). However, a sample from a 2 m thick ignimbrite (Emig) interbedded with red sandstones (Emvs) along this transect (Figure 3b) has been recently dated at 23.6±0.2 Ma (Ferrari et al., 2013). This age corresponds to the onset of the early Miocene ignimbrite pulse in the southern SMO (Scheubel et al., 1988; Ferrari et al., 2002, 2007, 2013; McDowell and McIntosh, 2012). Particularly, ignimbrites of this age make up the Las Canoas ignimbrite succession (Ferrari et al., 2002) exposed in the eastern part of the transect, which covers the reddish volcano-sedimentary sequence. Las Canoas succession is composed of a series of pink to grey, moderately indurated and slightly weathered ignimbrites (Emig), that contain small phenocrysts of plagioclase, biotite, alkali-feldspar and biotite (Figure 3c). Therefore, the volcaniclastic succession observed in the western part of the transect represents distal facies of the early Miocene volcanic succession exposed in the SMO core (Figure 7a).

A series of mafic dikes (Md), which vary in thickness and orientation, is observed at several locations along the transect cutting the Las Canoas ignimbrites and the volcaniclastic succession. The dikes are dark green, aphyric to porphyritic in texture, with plagioclase and less common hornblende phenocrysts. Most of them have been intruded along fault planes (Figure 3d). Striae and fault gouge (Fg) were observed along some dike walls, indicating that faults remained active after dike intrusion (Figure 3d). In some cases, dikes were cut and displaced by faults (Figure 3e). Intense alteration prevented radiometric dating on most of these mafic dikes. Nevertheless, we were able to obtain a 40Ar/39Ar age for one dike located ~6 km west of Jesús María (site Nay-21, Figure 4). This dike has an E-W orientation and cut an ignimbrite succession that can be correlated with the Las Canoas ignimbrite succession. Two laser step-heating experiments on groundmass concentrates (Figure 8a) yielded similar age spectra, with a decreasing staircase pattern. A plateau age of 23.44±0.23 Ma is defined by five consecutive fractions representing more than 70% of the 39Ar released. The staircase shaped age spectrum suggest the presence of excess argon, for this reason the preferred age was obtained combining all gas fractions obtained from both experiments on a correlation diagram (Figure 8b), which yields a 23.01±0.24 Ma isochron age. A summary of relevant information about 40Ar/39Ar dating is presented in Supplemental file 1. East of Jesús María, a N-S trending mafic dike was also observed cutting the Las Canoas ignimbrite succession and feeding a lava flow (Figure 3c). This dike was too altered to be dated but similar basaltic lavas were dated by Ferrari et al. (2002) at 21.3±0.3 Ma just 1.5 km East from this site (their sample TS-21). Based on these two ages and crosscutting relations, we consider that the mafic dikes observed along the eastern part of the transect are early Miocene in age. Basaltic dikes and flows of this age have been also reported for the Bolaños graben (Figure 1) (Nieto-Obregon et al., 1981; Scheubel et al., 1988; Ramos Rosique, 2013) and at the boundary between the SMO and the Trans-Mexican Volcanic Belt north of Guadalajara (Rossotti et al., 2002).

In the central part of the transect, the Las Canoas ignimbrite succession is overlain by the younger Nayar ignimbrite (Nig) succession (Figure 7a) (Ferrari et al., 2002), which consists of a series of welded ash-flow and ash fall tuffs, characterized by white to light yellow colors, composed of ash with phenocrysts of quartz, plagioclase, alkali-feldspar and biotite (Figure 3f). Several rhyolitic domes (Rd) are intercalated with or cap the Nayar ignimbritic succession (Figure 3g to 3i; Figure 7a). These domes, which post-date the Nayar succession, yielded ages between ~17.5 and 18.4 Ma (Figure 4) (Ferrari et al., 2002; 2013). In the Mesa del Nayar area most layers of this succession are horizontal or show only minor tilting (<10°), whereas they are tilted up to 35° to the west (Figures 2 and 3f). The maximum thickness of the Nayar succession is observed in the Mesa del Nayar area (Figure 3i), with at least ~800 m of ignimbrites (Figure 7a). The top and the base of the unit were dated by Ferrari et al. (2002) at 19.9±0.4 Ma and 21.1±0.3 Ma, respectively, implying that a thickness of almost 1 km was emplaced within ca. 1 m.y. The source of this succession has been associated with the formation of a series of NNW aligned calderas, interpreted on the basis of landforms, domes, and sedimentary deposits found in the Mesa del Nayar area (Ferrari et al., 2002).

Central transect: Aguamilpa dam

This relatively short transect runs for ~12 km in a WSW–ENE direction along roads following both sides of the Santiago river, downstream and west of the Aguamilpa dam (Figures 2 and 5). In this area, the Santiago river follows a complex accommodation zone, which separates the San Pedro–Acaponeta fault system to the north from the Pochotitán fault system to the south (Figure 2). The geology of the Aguamilpa dam area is dominated by a succession of well indurated, pink colored ignimbrites, typically rich in phenocrysts of plagioclase and/or biotite. The succession dips 26° to 50° to the W and WSW due to normal faulting (Figure 7b). Available ages for these ignimbrites range between 22.4 and 18.7 Ma (Rodríguez-Castañeda and Rodríguez-Torres, 1992, and references therein; Frey et al., 2002), at 19.9±0.4 Ma and 21.1±0.3 Ma, respectively, implying that a thickness of almost 1 km was emplaced within ca. 1 m.y. The source of this succession has been associated with the formation of a series of NNW aligned calderas, interpreted on the basis of landforms, domes, and sedimentary deposits found in the Mesa del Nayar area (Ferrari et al., 2002).

A series of subvolcanic bodies, which vary in composition from intermediate to felsic, are found below the ignimbrites (Figure 7b). Although field relations are not always clear, some of them are clearly intrusive and seem to have exploited the normal faults to ascend to a shallow level. Rodríguez-Castañeda and Rodríguez-Torres (1992) report a K-Ar age of 18.3 Ma for an granite body. Duque-Trujillo et al. (in press) report many subvolcanic intrusives along the SMO piedmont with ages between 22.3 and 18.1 Ma. Based on their geographical distribution, mineralogy, and field relationship with the ignimbrites, we consider that the subvolcanic bodies exposed near the Aguamilpa dam are part of the same subvolcanic suite.

Several rhyolitic domes cap the ignimbrites (Figures 2, 5 and 7b). Although no dates have been obtained, their stratigraphic position

286
suggests that they could correlate with those observed in the Estación Ruiz-Jesús María transect east of Mesa del Nayar, with ages between ~17.5 and 18.4 Ma. A large dome complex is also observed on the southwestern side of the Aguamilpa reservoir. Rodríguez-Castañeda and Rodríguez-Torres (1992) report a K-Ar age of 14.7 Ma for an andesite making up the peak of the complex (Picachos andesite). Although these domes were not mapped in detail, they do not appear faulted, suggesting they post-date the NNW striking normal fault systems.

A swarm of mafic dikes cross-cut the early Miocene ignimbrites along this transect. They are fine grained to aphyric, dark green in color and range between 1 to 4 m in thickness. Many of these dikes were dated both by K-Ar and $^{40}$Ar-$^{39}$Ar methods, yielding ages between 11.5 and 11 Ma (Damon et al., 1979; Soto and Ortega, 1982; Frey et al., 2007). These dikes are thus part of the regional pulse of mafic magmatism recognized along the whole eastern side of the Gulf, as described and discussed in Ferrari et al. (2013).

Southern transect: El Cajón – Sierra de Pajaritos
This transect goes from Santa María del Oro–El Cajón area, at the boundary between the Trans Mexican Volcanic Belt (TMVB) and the SMO (Figure 7c), to the Sierra de Pajaritos fault system, which bounds the eastern side of the Huajimic half graben (Figures 2 and 7d). This transect passes across the NNW striking Pochotitán fault system and the N-S striking Sierra de Alica fault system and, in its
Figure 3. a) NE-verging oblique reverse fault affecting volcanoclastic deposits (Emvs) at the base of the El Nayar ignimbrite succession; site Ruiz-08. eastern part, intersects the Sierra de Pajaritos fault system and El Roble accommodation zone (Figures 6 and 7c-7d). The geologic units observed along this transect are similar to those described in the other two transects.

The lower part of the sequence observed along this transect is constituted by a reddish volcano-sedimentary sequence (Emvs), mainly composed of sandstones and conglomeratic sandstones with abundant clasts of andesitic volcanic rocks (Figures 3j and 7c). Interbedded within this sequence are ignimbrites (Emig) that range in thickness from 2 to >50 m, which become dominant up-section. Ignimbrites vary in composition; they are characterized by different matrix color, phenocrysts, rhyolite dome, andesites and lithics of different compositions. Also, interbedded in the volcano-sedimentary sequence are andesitic lava flows, usually less than 5 m thick. These are fine to medium grained, usually porphyritic with hornblende and plagioclase phenocrysts. On the western side of the El Cajón reservoir, the dip of this sequence varies greatly, but does not exceed 30°; strata mainly dips west with variation from WSW to NNW. On the eastern side of the El Cajón reservoir, rocks dips mostly to the east, defining a broad anticline with a N-S striking axial plane parallel to the valley (Figures 3k and 7c). This is part of a series of left-stepping en-echelon folds developed by left-lateral transpression along the boundary between the SMO and the TMVB, which would have been active between 14.5 and 11.5 Ma (Ferrari, 1995; Ferrari et al., 2002). North of the transect, at Sierra de Alica and Sierra de Pajaritos, rocks dip monotonously to the east because of N-S striking west-dipping normal faults (Figures 2, 3l and 7d).

Despite the lack of radiometric ages, in the geologic maps of the Mexican Geological Survey (SGM, 1996, 1998), the lower part of the succession in this area is interpreted as Paleocene to Oligocene in age. Middle and late Eocene ages have been reported for a rhyolite lava and an ignimbrite northwest of Santa María del Oro and southern Sierra de Pajaritos, respectively (Damon, et al., 1979; Frey et al., 2007), but the geologic context of these samples is unknown. We dated detrital zircons separated from the sandy matrix of the reddish volcano-sedimentary succession toward the base of the succession (sample Cajón 06, Figure 9). The dated layer include well rounded green and red clasts of porphyritic volcanic rocks and overlies a faulted sequence of red sandstones and siltstones (Emvs), in turn deposited over a basaltic lava flow (Figures 3m and 8). Twenty-seven grains yielded ages in the range between 26 and 22 Ma, with a peak at ~23.5 Ma, indicating that this sequence is correlative with that found in the lower part of the Estación Ruiz-Jesús María transect.

Figure 4. Geological map of the Estación Ruiz – Jesús María transect showing fault kinematics and right-dihedra solution obtained from field data. On the right-dihedra diagrams, black quadrants indicate tension and white quadrants indicate compression. The Ruiz 06 dihedra diagram (blue compressive quadrants) represents a local situation (see text for explanation). Minor faults interpreted in this work, and main fault traces from Ferrari et al. (2013). Dip directions from Ferrari et al. (2002, 2013), 1:250.000 scale geologic maps of Servicio Geológico Mexicano, Escuinapa and Tepic sheets, (SGM, 1998, 1999), and Google Earth observations. Key for ages as in Figure 2.
The upper part of the sequence is dominated by several ignimbrites that resemble the Nayar succession (Figure 7c). These are white to light yellow ash flow tuffs, with phenocrysts of plagioclase, K-feldspar, quartz and biotite in a matrix composed mainly of ash and, less commonly, pumice, which may constitute up to 30% of the rock. $^{40}\text{Ar} - ^{39}\text{Ar}$ ages of 20.5±0.4 Ma and 20.7±0.2 Ma (Ferrari et al., 2002; 2013) confirm that these ignimbrites are distal facies of the Nayar succession.

On the deepest part of the Santiago river, several subvolcanic bodies were found intruding the ignimbrites. Using U-Pb in zircon geochronology, Duque-Trujillo et al. (in press) dated a quartz-dioritic and a granitic subvolcanic body from the footwall of the Pochotitán fault system at 18.1±0.2 and 21.3±0.43 Ma, respectively (Figure 6).

A series of mafic dikes cuts the whole volcanic sequence in the El Cajón-Sierra de Pajaritos region. These dikes vary in width and orientation, but have similar appearance, being dark green in color, aphyric to porphyritic, with plagioclase and less often hornblende phenocrysts. Most of them are moderately altered and are surrounded by baked layers of country rock, as in the Estación Ruiz-Jesús María transect (Figure 3d). Dike intrusion mostly occurred along faults, which in some cases were also active after the intrusion, displacing some of the dikes. Damon et al. (1979) reported an age of 11.1 Ma for a mafic dike east of El Cajón reservoir. This age, and the fact that the mafic dikes were observed cutting all the early Miocene ignimbrites, indicate that they are coeval with those observed in the Aguamilpa dam area to the north (Figure 5) and with the regional pulse of late Miocene mafic volcanism recognized on the eastern side of the Gulf (Ferrari et al., 2002; 2013).

Figure 5. Geological map of the Aguamilpa Dam transect. Minor faults interpreted in this work, and main fault traces from Ferrari et al. (2013). On the right-dihedra diagrams, black quadrants indicate tension and white quadrants indicate compression. Dip directions from Ferrari et al. (2002, 2013), 1:250.000 scale geologic maps of Servicio Geológico Mexicano, Escuinapa and Tepic sheets, (SGM, 1998; 1999), and Google Earth observations. Key for ages as in Figure 2.
FIELD MEASUREMENTS

A total of 160 faults and 144 dikes were measured along the three transects described in the previous section. Faults and fractures were identified at the outcrop scale, paying particular attention to areas where the roads cross the main fault systems. The orientation of faults and fractures were measured using a stratum compass, and fault planes were inspected for fault-slip kinematic indicators (e.g., slickenlines). Each fault-slip measurement consisted of strike and dip of the fault plane and trend and plunge of the slickenlines. Faults and kinematic indicators were observed at 24 structural outcrops allowing for a dynamic analysis. We performed a paleo-stress analysis using the right-dihedra method of Angelier (1979, 1984) (Table 1; Figures 4-6, and 10) using the tectonicsFP software (Ortner et al. 2002). The sum of right-dihedra diagrams defines tension and compression quadrants similar to those used in the visualization of earthquake focal mechanisms. The maximum and minimum stress tensors axis, σ1 and σ3, should be located inside these quadrants (Angelier, 1994). To define the degree of fitting of the data set, right-dihedra density plot from each transect (obtained using the stereo32 software) are shown together with the fault-slip data in Figure 10. The right-dihedra method was applied only at sites where a minimum of four faults with kinematic indicators was observed. However we included three sites (Ruiz 26, Nay 24, and Cam 32) where less than four kinematic indicators were measured because at these sites a major fault plane with homogeneous kinematic indicators was present. All the measured faults and kinematic indicators are contained in the 23.5 Ma and younger volcano-sedimentary sequence, ignimbrites, and mafic dikes. A synthesis of faults, slickenlines, and mafic dikes measurements is presented in Figure 11.

Faults

We summarize the orientations of faults measured along each of the three transects and illustrate the three broad categories of observed fault orientations (Figure 11a–11c). The dominant orientation is N-S to NNW-SSE, which corresponds to the main extensional structures affecting the southern SMO (Ferrari et al., 2007, 2013), and produced up to 100 km long and 20 km wide grabens and half grabens. In the study area, these faults displace the early Miocene ignimbrite succession, forming the Jesús María, Sierra de Alica, and Huajimic half grabens, with offsets up to 1.5 km (Figures 1, 7a, 7c and 7d).

A second dominant fault orientation is NW-SE and corresponds to the San Pedro-Acaponeta and Pochotitán fault systems, located on the westernmost part of the SMO, bordering the coastal plain (Figures 2 and 6). The offset along these faults systems is at least 1 km as they lower the SMO ignimbrites beneath the coastal plain (Figure 7b).

A third group of faults, almost orthogonal to the previous two groups has E-W and NE-SW orientation. These faults correspond to accommodation zones, which separate different segments of the rift
Miocene faulting in Sierra Madre Occidental: initial rifting of the southern Gulf of California

Figure 7. Geological profiles along the studied transects. Key for ages as in Figure 4.
characterized by opposite tilting direction (Ferrari et al., 2002; 2013). Axen (1995) also observed that the Main Gulf Escarpment in Baja California is segmented by similar accommodation zones.

The field measurements (Figure 11a-11c) show some variation with respect to the large-scale faults and lineations (Figures 4 to 6). This difference is likely due to the presence of several second order structures seen at outcrop scale, such as Riedel shears and tension gashes, which are normally associated with the main structures.

**Estación Ruiz-Mesa del Nayar transect**

Along this transect, the dominant fault orientation is N-S to NNW-SSE with a dominant dip to the west (Figure 4, Figure 11a). Large blocks of the SMO ignimbrite sequence are tilted ~20° down to the east, with offsets varying from meters to hundreds of meters (Figure 7a). Most faults have normal dip-slip kinematics, but a right-lateral (?) strike-slip component can be observed near the San Pedro-Pochotitán fault system, and is not observed further east (Figure 4). One of the N-S striking faults is capped and sealed by a rhyolitic dome (site Ruiz-34) (Figures 3h and 4) dated at 18.4±0.3 Ma by U-Pb in zircon and 17.57±0.19 Ma by 40Ar/39Ar in biotite (Ferrari et al., 2013). Assuming this single fault is representative of the population of N-S striking faults, this relation implies that the N-S faults where not active after ~18 Ma.

The San Pedro-Pochotitán fault system is present on the westernmost portion of this transect. The faults belonging to this system are characterized by a NW-SE orientation with primarily normal dip-slip kinematics, although a dextral strike-slip component was observed in many of the measured faults. Most of the faults dip to the west, tilting the ignimbrites and sediments of the SMO ~20° down to the east (Figure 7a).

NE-SW and E-W striking faults are also present in this transect. These faults control the El Fraile and El Naranjo rivers (Figure 4). From the western part of Mesa del Nayar to Jesús María, the dominant structures are NE-SW striking faults, NW dipping normal faults located on the southern side of the El Fraile river (Figure 3g), and shorter faults with variable dip on the northern side (Figure 4). The El Fraile river faults have a prominent morphological expression, and Ferrari et al. (2002; 2007) interpreted them as part of a caldera rim, with the area to the north of the river forming the caldera interior, filled by numerous ignimbrite sheets (Figure 4). On the western part of the transect, along El Naranjo river, we observed a series of E-W striking and south dipping faults, with a dominant right-lateral strike-slip motion (Figure 4). Some minor reverse faults (blue stereoplot in Figure 4) affecting the volcano-sedimentary and ignimbrite rocks have been interpreted as local restraining segments within the strike-slip system (sites Ruiz-05 and 06 in Figures 3a and 4). The ENE-WSW striking El Fraile fault system and the E-W striking El Naranjo fault system could represent an accommodation zone, likely related to basement discontinuities. At least in some part of the transect, these transverse structures represent a boundary between zones with opposite tilting of the volcano-sedimentary sequence (Figure 2).

**Aguamilpa Dam transect**

Although the Aguamilpa Dam transect runs along the northern part of the NNW striking Pochotitán fault system, several fault orientations where found. NNE-SSW striking faults are the most abundant structures observed in outcrops (Figure 11b). Most of them are minor faults, with only one major fault showing normal kinematics with a left-lateral strike-slip component of motion (Figure 5). We speculate that these faults could be Riedel structures (R') formed by the activity of the Pochotitán fault system. E-W faults were also observed with dominant normal dip-slip kinematics and a consistent left-lateral component of motion. The E-W faults are arranged in a left stepping array (Figures 2 and 4). Together with the NE-SW faults, they inter-

Figure 10. Fault planes with fault-slip data, dihedral density plot and resultant right-dihedra calculations for each structural site shown in Figures 4 to 6.
rupt the continuity of the Pochotitán fault system, which to the south consists of a series NNW-SSE striking west dipping normal faults. To the north, the northern termination of the Pochotitán fault system is slightly rotated counterclockwise and display a minor right-lateral strike-slip component of motion. As a whole, these structures define a complex accommodation zone along which the Santiago river found its way to the coast. The N-S faults observed on this transect are minor normal faults, mostly dipping east, and some of them show a small left-lateral component (Figure 5).

**El Cajón Dam-Sierra de Pajaritos transect**

Along the El Cajón-Sierra de Pajaritos transect, the dominant faults strike from NNW to NNE (Figure 11c). These faults are primarily normal, with occasionally right lateral strike-slip component (Figure 6). This group of faults is parallel to the main ~N-S structure forming the Huajimic and Camotlán half grabens (Figures 3l, 6 and 7d). The westernmost part of the transect is dominated by the NNW-SSE striking Pochotitán fault system, which tilt early Miocene ignimbrites down to the SWS (Figure 7c). These early Miocene ignimbrites are covered by younger mafic lavas (11 to 10 Ma) of the TMVB (Ferrari et al., 2000b, 2002).

In the eastern part of the transect (Figure 7d), the Sierra de Pajaritos is bounded by two main fault systems: the N-S to NNE-SSW west-dipping faults which form the eastern edge of the Huajimic half graben and the E-W to ENE-WSW faults of El Roble accommodation zone (Figure 6, Figure 11c). These two fault patterns was also observed at outcrop scale. The kinematics of these faults were difficult to establish due to the lack of kinematic indicators. Nevertheless, at site Cam 44 (Figure 6) kinematic indicators corroborate the left lateral strike-slip motion of these faults (Table 1).

**Figure 11.** Pole density plot and rose diagram for faults (panels a-c) and dikes (panels d-f) measured in the study area. Diagrams are equal angle projection, lower hemisphere. Rose diagram interval: 20°, dip angle interval: 10°, maximum values represent the percentage of the data grouped in the maximum value.
Mafic dikes

Along the three transects we observed a large number of mafic dikes. The most common dike orientation is NNW-SSE to NW-SE, although other orientations were found locally (Figure 11d–11f). Dike orientation is important to estimate the least principal stress at the time of intrusion, which tends to be normal to the strike of a subvertical dike (Pollard, 1987). We recognized three groups of dike orientations: NNW to NW striking, E-W striking and N-S to NNE-SSW striking.

Dikes striking NW to NNW are by far the most common (Figure 11d–11f). These are mostly located along the western part of the northern and southern transects (Estación Ruiz-Jesús María and El Cajón Dam–Sierra de Pajaritos transects) (Figure 4 and 6). They are also common in the Aguamilpa dam transect (Figure 5). Most of these mafic dikes have subvertical dip (between 80 and 90°) and usually intrude along previously existing normal faults, which commonly remain inactive after intrusion. Only some of the faults show evidence of reactivation, such as fault gouges and striated dike walls (Figure 3d), and at least in one case a dike was observed to be cut by the same fault it intruded (Figure 3e). Several of these dikes have been dated between 11.5 and 11 Ma (Damon et al., 1979; Clark et al., 1981; Soto and Ortega, 1982; Frey et al., 2007).

A second group of dikes, striking E-W and dipping 70-90° (dipping both N and S) was found in the eastern part of the Estación Ruiz-Jesús María transect and, to a lesser extent, in the El Cajón dam-Sierra de Pajaritos transect (Figure 9d and 9f). They cut the lower ignimbrite and volcano-sedimentary sequence and do not seem to have intruded along pre-existing faults. At site Nay 13 an E-W striking dike was observed cutting the ignimbrite sequence and feeding into an overlying basaltic lava flow (Figure 3c).

Some scattered dikes, striking NNE-SSW and NE-SW were also found locally in the Aguamilpa Dam and the El Cajón-Sierra de Pajaritos transects (Figure 11e and 11f). Usually, these dikes are associated with faults observed in these two areas (Figure 11b and 11c).

DISCUSSION

The meso-scale faults observed along the studied transects can be grouped into three sets, and can be associated to the two extensional phases that have occurred since the late Oligocene, defined in Ferrari et al. (2013). The dominant fault orientation is ~N-S striking, with subordinate NNW-SSE to NW-SE and ~E-W to NE-SW orientations (Figure 11a–11c).

The N-S fault set corresponds to the major N-S striking structures located in the eastern part of the study areas: the Jesús María, Sierra de Alica, Sierra de Pajaritos, and Puente de Camotlán half-grabens. The kinematic analysis of these N-S striking faults indicates that they have a dominantly normal motion with a minor strike-slip component. We illustrate the relationship between fault plane dip and the striae plunge contained on each fault plane (Figure 10), which determine the kinematics of the faults (Figure 12). The data from the eastern and western part of the northern and southern transects were plotted separately. Faults measured in the eastern part of these transects (Mesa del Nayar and Sierra de Pajaritos areas) are dominated by pure normal motion and, to a lesser extent, by almost pure strike-slip motion, with very rare oblique slip faults (Figures 12b and 11e). Field relations of dated units show that the activity of the N-S striking faults began during the emplacement of the ~23.5 Ma Las Canoas ignimbrite succession and was complete by ~18 Ma (Ferrari et al., 2013). The direction of the minimum principal stress (σ3) calculated for the ~N-S structures indicate that this deformation phase was characterized by E-W to ENE-WSW crustal stretching (Figure 13).

The second set of faults, characterized by NNW to NW orientations is mostly found in the western part of the transects (Figure 11a–11c) and correspond to the San Pedro-Acaponeta and Pochotitán fault systems. These fault systems defines the western limit of the SMO (Figure 2) and tilt the ignimbrite sequence as much as 35° down to the E-NE. We consider that the activity of these NNW to NW faults began at ca. 21...
Ma because they cut the El Nayar ignimbrite sequence and expose some shallow intrusive bodies with ages between \textit{ca.} 20 and 17 Ma (Ferrari \textit{et al.}, 2002; Duque-Trujillo, \textit{et al.}, in press). The minimum age estimate for the activity of these faults is constrained by a series of flat-lying basaltic lavas as old as 10.5 Ma that are found covering the tilted ignimbrites along the coastal plain (Ferrari \textit{et al.}, 2013, and references therein). Several of these faults have a pure normal displacement (Figures 12a, 11c and 11d), with an ENE-WSW orientation of the minimum principal stress (\(\sigma_3\)), indicating a slight counterclockwise rotation from the E-W stretching direction determined on the N-S striking faults mapped in the eastern part of the study area (Figure 13). Several faults measured along the San Pedro-Acaponeta and Pochotitán fault system are oblique-slip with a right-lateral strike-slip component (Figure 12a, 12c and 12d). The majority of these faults are found in proximity of accommodation zones (El Naranjo, Aguamilpa, and El Roble; Figures 4, 5, 6) and can be associated to block rotation and/or interaction with transverse structures of these shear zones. Alternatively, if these systems were active at the same time of the ~N-S fault systems, the E-W extension that characterize the early Miocene regime may have induced a right-lateral oblique motion on these NNW striking planes.

The younger group of mafic dikes emplaced along the western SMO, support the dominant extensional kinematics deduced for the San Pedro-Acaponeta and Pochotitán fault systems. These dikes are NNW to NW striking (Figure 11d-11f). Assuming that they were emplaced orthogonal to the former \(\sigma_3\) (Delaney, \textit{et al.}, 1986), they indicate an ENE or NE trending minimum principal stress (\(\sigma_3\)) at the time of emplacement. As mentioned before, these dikes were emplaced between 11.5 and 11 Ma, at the end of the period of activity of the San Pedro-Acaponeta and Pochotitán fault systems. Due to the preferred orientation of the San Pedro-Acaponeta and Pochotitán fault systems (NNW to NW), a ENE to NE oriented minimum principal stress would had been expressed with normal kinematic faults along them, instead of right-lateral. This implies that these fault systems had a minimum oblique, right-lateral motion until ca. 11 Ma. This also suggests that if right-lateral transtension began within the Gulf area prior to \textit{ca.} 11 Ma (e.g., Fletcher \textit{et al.}, 2007; Sutherland \textit{et al.}, 2012), the southeastern margin of the Gulf was not significantly affected. Such hypothesized dextral transtensional deformation must have occurred further west of our study area, and possibly preserved beneath that coastal plain or the offshore rifted continental shelf. At a regional scale, an initial ~E-W extension was accommodated along N-S striking faults, which then turned into a more ENE extension, accommodated along NNW faults which only affected the westernmost flank of the SMO. Ferrari \textit{et al.} (2013) and Bryan \textit{et al.} (2014) proposed that this tectonic change could have taken place between 21 and 18 Ma, which is now confirmed by the counterclockwise rotation of the minimum principal stress (\(\sigma_3\)) determined in this work.

The third set of faults observed strikes E-W, ENE-WSW or NE-SW and have a transverse orientation with respect to the other two sets (Figure 2). Although this kind of structures has already been reported for the southern SMO (Henry and Aranda-Gómez, 2000; Ferrari, \textit{et al.} 2002), they are uncommon. The \textit{ca.} 23.01 Ma age for a ~E-W striking
dike found in the Mesa del Nayar-Jesús María area suggest that these faults may be the oldest structures in the study area. However, in other cases these faults appear contemporaneous with the other two sets, which suggest that they represent transfer or accommodation zones, which separate different domains of extension along the western SMO. Transfer zones are mostly formed along a sharp contrast in amount or style of deformation between rift domains (Faulds and Varga, 1998). Nevertheless, the location of these zones could be controlled by the presence of ancient shear zones, as observed in other rifts (e.g., East African Rift and Gulf of Suez, Rosendahl, 1987; Moustafa, 1996). In the study area, the location of these ~E-W to NE-SW structures may be related to pre-existing basement structures, which could have been reactivated during the progressive E-W to WSW-ENE extension that accompanied the initial rifting of the Gulf of California. Indeed, several E-W to NE-SW striking structures affecting the Cretaceous to Paleogene basement have been reported in the SMO (Henry, 1986; Horner and Enriquez, 1999; Horner and Steyerer, 2005). These structures include folds, thrust faults, foliations, tension gashes, shear fractures, and fault zones, which constitute structural weaknesses prone to be reactivated as rift-related accommodation zones (Henry and Aranda-Gómez, 2000; Ferrari, et al. 2002). Although some of the ~E-W structures mark a reversal in the tilting direction of the ignimbrites (e.g., El Roble accommodation zone), this is not a rule in the study area (e.g., Aguamilpa and El Naranjo), where some transverse fault zones seem to locally relay the deformation rather than represent a change in the structural style, as defined by Axen (1995) in Baja California. In particular, the El Naranjo (Figure 5) and Aguamilpa (Figure 6) accommodation zones serve as the structural connection across a broad, ~10 km-wide left step between the Pochotitán and San Pedro-Acaponeta fault systems, while block tilting is everywhere down to the E and ENE. In the case of the El Roble fault zone (Figure 6), it separates the extensional structures associated to the Gulf of California with a complex transpressional zone associated with the interaction between the Jalisco block and the southernmost end of the SMO (Ferrari, 1995; Ferrari et al., 2002).

CONCLUDING REMARKS

We have presented the first detailed structural study of the fault systems that affect the southwestern part of the SMO in northern Nayarit, which constrains the kinematics of the initial rifting of the southeastern margin of the Gulf of California rift. Three main families of faults were identified: 1) A group of ~N-S striking faults, associated to the province bounding structure along the western edge of the SMO, with activity bracketed between 24 and 18 Ma; 2) a family of NNW-SSE to NW-SE striking faults associated to the San Pedro-Acaponeta and Pochotitán fault systems in the western part of the SMO, whose activity is constrained between ~21 and 11 Ma; 3) an E-W to ENE-WSW striking group of faults, which seems to be associated to pre-existing basement structures reactivated as accommodation zones during early and middle Miocene rifting phases.

The kinematic analysis and right-dihedra calculation based on the collected fault dataset, the orientation of extension-related dikes, in addition to the age of rocks affected and unaffected by faults allow us to infer that the minimum principal stress (σ3) was oriented ~E-W during the early Miocene (24–18 Ma) phase and subsequently rotated slightly counterclockwise to ENE-WSW during the middle Miocene (18–11 Ma) phase. Deformation kinematics indicates a dominant normal faulting and, to a lesser extent, oblique faulting regime along the southeastern SMO. Fault obliquity can be associated to fault interaction in proximity to accommodation zones as observed near the El Roble accommodation zone in Sierra de Pajaritos. Also, some transpressional motion along NNW striking faults during the early Miocene ~E-W extension cannot be excluded. Our data do not support the hypothesis that significant right-lateral transpressional motion was accommodated in the early to middle Miocene (24–11 Ma) in the southeastern margin of the Gulf of California. Rather, these data support the hypothesis that the onset of dextral transtension in the Gulf of California was delayed until the onset of regional dextral oblique motion between the Pacific and North American plates at ca. 12.5 Ma (e.g., Stock and Hodges, 1989; Bennett and Oskin, 2014).

ACKNOWLEDGMENTS

The present work was supported by grant CONACYT 82378 (to Ferrari), CONACYT also supported Duque-Trujillo PhD scholarship. We thank I. Loza Aguirre, P. Botero Santa, G. Antillón Mata, M. Michell for discussion and field assistance. C. Ortega, M.A. Garcia are thanked for assistance in U-Pb and Ar-Ar dating, respectively. A.S. Rosas Montoya, V.M. Pérez Arroyo, G. Rendón and L. Gradilla helped with Ar-Ar sample preparation. Reviews by Scott Bennett, an anonymous reviewer and associated editor Angel Nieto Samaniego greatly helped to improve the quality of the manuscript. T. Orozco-Esquível is thanked for thoroughly reviewing the final version of the paper.

APPENDIX A. SUPPLEMENTARY MATERIAL
